Pure bacterial cultures were isolated from a highly enriched denitrifying consortium previously shown to anaerobically biodegrade naphthalene. The isolates were screened for the ability to grow anaerobically in liquid culture with naphthalene as the sole source of carbon and energy in the presence of nitrate. Three naphthalene-degrading pure cultures were obtained, designated NAP-3-1, NAP-3-2, and NAP-4. Isolate NAP-3-1 tested positive for denitrification using a standard denitrification assay. Neither isolate NAP-3-2 nor isolate NAP-4 produced gas in the assay, but both consumed nitrate and NAP-4 produced significant amounts of nitrite. Isolates NAP-4 and NAP-3-1 transformed 70 to 90% of added naphthalene, and the transformation was nitrate dependent. No significant removal of naphthalene occurred under nitrate-limited conditions or in cell-free controls. Both cultures exhibited partial mineralization of naphthalene, representing 7 to 20% of the initial added 14C-labeled naphthalene. After 57 days of incubation, the largest fraction of the radiolabel in both cultures was recovered in the cell mass (30 to 50%), with minor amounts recovered as unknown soluble metabolites. Nitrate consumption, along with the results from the 14C radiolabel study, are consistent with the oxidation of naphthalene coupled to denitrification for NAP-3-1 and nitrate reduction to nitrite for NAP-4. Phylogenetic analyses based on 16S ribosomal DNA sequences of NAP-3-1 showed that it was closely related to Pseudomonas stutzeri and that NAP-4 was closely related to Vibrio pelagius. This is the first report we know of that demonstrates nitrate-dependent anaerobic degradation and mineralization of naphthalene by pure cultures.

Hydrocarbon contamination in sediments has been the subject of continuous environmental and human health concern over the last few decades. Polycyclic aromatic hydrocarbons (PAHs), components of petroleum waste, airborne combustion particulates, and creosote are particularly persistent in sedimentary subsurface environments due to their relatively low aqueous solubilities, low volatility, and high affinity for sediment particles. PAH-contaminated sediments are a concern to human health because of the potential for exposure through the consumption of contaminated seafood stocks (19, 23, 33, 37). Fish and shellfish frequently bioaccumulate PAHs to concentrations that are several orders of magnitude greater than their aqueous solubility (2). The human health effects of PAH exposure are well documented. Acute exposure effects range from skin and lung irritation to cyanosis (2). Exposure to some PAHs has been implicated as carcinogenic and tumorigenic to both humans and wildlife (2). Because of these human health concerns, accurate estimates of the persistence of PAHs in the environment are important in assessing the risk presented by PAH contamination.

A key parameter affecting the fate of PAHs in the environment is the extent of loss due to mechanisms of biodegradation. The ability of aerobic microorganisms to degrade naphthalene, phenanthrene, and other low-molecular-weight PAHs is well known (5). However, subsurface organic-impacted sediments are commonly anaerobic. Although PAHs typically had been thought to be recalcitrant to biodegradation without oxygen (e.g., references 3, 11, 14), recent studies have demonstrated PAH degradation under sulfate-reducing (7, 8, 30, 38) and nitrate-reducing (22, 24, 25, 30; K. J. Rockne and S. E. Strand, submitted for publication) conditions. Because PAHs can be biodegraded without oxygen, their persistence in anaerobic environments might be less than was previously thought. While it has been shown that PAHs are degraded anaerobically, little is known about the microorganisms responsible for this activity. With the exception of a recent report (22), pure cultures have not been reported thus far with the ability to degrade PAHs under anaerobic conditions. Furthermore, nitrate-dependent PAH transformation by microbial isolates has never been demonstrated. Virtually nothing is known about the types of bacteria responsible for anaerobic PAH biodegradation. Further knowledge of the biochemical reactions, enzymes, and genetics of anaerobic PAH biodegradation would be facilitated by the isolation and study of pure cultures. In this study we describe several anaerobic naphthalene-degrading pure cultures isolated from a highly enriched PAH-degrading, nitrate-reducing culture originating from a PAH-contaminated site.

MATERIALS AND METHODS

Isolation of pure cultures. The source of inoculum for these isolations was a highly enriched consortium of microorganisms obtained from a fluidized bed reactor (FBR) originally seeded with PAH-contaminated marine sediment from Eagle Harbor in Puget Sound, Wash. (30; Rockne and Strand, submitted). The FBR was operated by continuous feedings of low concentrations of naphthalene, phenanthrene, and biphenyl in the presence of nitrate, as previously described (30). Samples from the FBR were transferred to serum bottles containing anaerobically prepared artificial seawater (ASW) (29), plus nitrate (2 mM), and biologically prepared artificial seawater (ASW) (29), plus nitrate (2 mM), and biodegradation would be facilitated by the isolation and study of pure cultures. In this study we describe several anaerobic naphthalene-degrading pure cultures isolated from a highly enriched PAH-degrading, nitrate-reducing culture originating from a PAH-contaminated site.

The cultures were incubated for 90 days (in the case of the naphthalene-fed cultures) with three refeedings of naphthalene as described elsewhere (Rockne and Strand, submitted). Results from the biphenyl- and phenanthrene-fed cultures were inconclusive, so we focus here on the naphthalene-fed cultures. Samples taken from the naphthalene-fed bottles were streaked onto modified anaerobic M-R2A agar plates (6) adjusted for sea salts concentrations and amended with KNO3 (5 mM). The plates were inoculated and incubated at room temperature (20 to 25°C) in an anaerobic glove box with a headspace consisting of 80% N2, 18% CO2, and 2% H2. Aseptic and strict anaerobic techniques were used throughout this study (17).

Colonies from the plates were removed with an inoculating loop scraped once over the culture broth. Cells were then transferred to broth tubes containing ASW (20 ml) plus 1 mM nitrate. The headspace for these and all further anaerobic bottle incubations consisted of oxygen-free nitrogen and were incubated at room temperature (20 to 25°C). Naphthalene was added to the medium using small sections of sterile glass fibr filters containing naphthalene (1% w/v in methylene chloride) and allowing the methylene chloride to evaporate. The final naphthalene concentration added was 15.6 μM, which resulted in an aqueous equilibrium concentration of 12 to 12.5 μM.

After incubation in liquid cultures (6 to 8 weeks), serial washes of deionized water (10 ml) and methanol (10 ml) to remove radiolabel from the clarified phase and nonpolar radiolabel (e.g., naphthalene) sorbed to the cells. The extracted filter was then placed in an acid fumer for removal of any absorbed 14CO2 (1), transferred to a scintillation vial (20 ml) with scintillation cocktail (20 ml; Ecolume) and counted by using HPLC with UV detection. The extracted filter was then placed in an acid fumer for removal of any absorbed 14CO2 (1), transferred to a scintillation vial (20 ml) with scintillation cocktail (20 ml; Ecolume) and counted by using the LSC. The total activity was corrected for residual radiolabel determined by fastDNAml (26).

The initial naphthalene concentrations were measured because of the potential for residual naphthalene carryover in the culture fluid during preincubation with naphthalene. All cultures were incubated in duplicate with control bottles consisting of [U-14C]naphthalene-containing sterile ASW. Supernatant samples were removed to determine initial naphthalene concentrations and the 14C specific activity. The test bottles were placed in an anaerobic glove box for incubation. At time points during incubation, aliquots (2 ml) of the culture samples were removed to determine initial nitrate and naphthalene concentrations and amended with KNO3 (5 mM). The plates were inoculated and incubated at room temperature (20 to 25°C) in an anaerobic glove box with a headspace consisting of 80% N2, 18% CO2, and 2% H2. Aseptic and strict anaerobic techniques were used throughout this study (17).

Cultures that demonstrated naphthalene transformation and nitrate reduction were restreaked for purity onto sea salts M-R2A plates. Cultures growing on naphthalene were grown on anaerobic ASW (20 ml) with purfied cultures also inoculated into ASW containing nitrate (5 mM), and pyruvate (3.4 M). The methylene chloride was allowed to evaporate prior to addition of the cells. The extracted filter was then placed in an acid fumer for removal of any absorbed 14CO2 (1), transferred to a scintillation vial (20 ml) with scintillation cocktail (20 ml; Ecolume) and counted by using the LSC. The total activity was corrected for residual radiolabel determined by fastDNAml (26).

The data sets were analyzed using several phylogenetic methods. Maximum-likelihood and parsimony analyses were performed by fastDNAml (26) and PAUP 3.0 (35), respectively. Programs used in the neighbor-joining analysis were accessed from the RDP (21). Ribosomal Database Project (RDP) version 5.0 ALIGN_SEQUENCE program Seq-App 1.9a, 1992) and were initially aligned with similar sequences by the Deoxy Terminator Cycle Sequencing kit (Applied Biosystems, Foster City, Calif.) using standard techniques (31).

Nucleotide accession numbers. The nearly complete 16S rDNA sequences for isolates NAP-3-1 and NAP-4 were deposited in GenBank with the following accession numbers: AF064636 and AF064637. The accession numbers of all the microbial cultures used in the construction of the phylogenetic tree are as follows.
RESULTS

General characteristics of the pure cultures. Three pure cultures were obtained in this study: NAP-4, NAP-3-1, and NAP-3-2. These cultures were all gram-negative rods (Table 1). NAP-3-1 and NAP-3-2 were catalase and oxidase positive, whereas NAP-4 was oxidase negative and only weakly catalase positive. All cultures were salt tolerant, and NAP-4 had an apparent requirement for greater than 3.5 ppt salinity for growth on M-R2A under the conditions of the assay. Gas production was observed for NAP-3-1 after 6 days of incubation in the denitrification assay. Isolate NAP-3-1, which degrades naphthalene, was confirmed to be a denitrifier by measuring N₂ production in the denitrification assay. Isolate NAP-3-2 grew on the denitrification medium but did not produce measurable quantities of gas. Similarly, isolate NAP-4 did not produce gas in the denitrification medium, but unlike NAP-3-2, NAP-4 grew poorly on the medium. Significant accumulation of nitrite (2 mM) occurred with isolate NAP-4. No nitrate remained in any of the cultures, and no nitrite was detected for isolates NAP-3-1 and NAP-3-2. All cultures grew on M-R2A both aerobically and anaerobically with nitrate, but only NAP-4 grew on M-R2A anaerobically without nitrate present.

Naphthalene transformation by pure cultures. The three strains were assayed for naphthalene and nitrate transformation in liquid cultures. After 18 days, the naphthalene-fed isolates demonstrated a loss in naphthalene concentration along with nitrate removal (data not shown). Isolate NAP-4 removed more than 33% of the naphthalene and 30% of the nitrate relative to the uninoculated control. Similarly, both NAP-3-1 and NAP-3-2 removed 22% of the naphthalene, with 22 and 25% of the nitrate reduced, respectively, to the uninoculated control. All three cultures contained small amounts of nitrite (data not shown). No significant losses of nitrate or aqueous-phase naphthalene were observed in the uninoculated naphthalene-containing control. The remainder of this study was focused on isolates NAP-3-1 and NAP-4 since NAP-3-2 demonstrated a rate of naphthalene degradation similar to that of NAP-3-1.

Nitrate-dependent naphthalene transformation and mineralization. Isolates NAP-4 and NAP-3-1 both exhibited nitrate-dependent naphthalene transformation (Fig. 1) after pregrowth on pyruvate or acetate, respectively. No statistically significant ($P = 0.05$) loss in naphthalene was measured in the NAP-3-1 culture under nitrate-limiting conditions compared to cell-free controls after 57 days of incubation. NAP-4 had a small but significant loss of naphthalene in the absence of nitrate. In the presence of nitrate, isolates NAP-4 and NAP-3-1

The average of duplicates ± the standard error of the mean (SEM), indicated by error bars, is shown.
Phylogenetic analysis. Comparison of the complete 16S rDNA sequences of NAP-3-1 and NAP-4 indicated that they were both phylogenetically similar to bacteria in the gamma proteobacteria group but were distant from each other within the group (Fig. 3). NAP-4 was phylogenetically similar to Vibrio pelagius (99.2% homology), which reduces nitrate to nitrite, and other Vibrio spp. NAP-3-1 was also in the gamma proteobacteria and was most closely related phylogenetically with Pseudomonas stutzeri (99.7% homology), as well as with P. putida and P. aeruginosa. These bacteria are in rRNA group I of the Pseudomonadaceae and are well known aerobic aromatic compound degraders (9, 36). P. aeruginosa is a denitrifier able to use nitrate, nitrite, or nitrous oxide as terminal electron acceptors (9). P. putida is not a denitrifier and does not degrade toluene under oxygen-limited conditions (2 mg of O₂ liter⁻¹), either with or without nitrate (naphthalene degradation was not assayed in that study [20]).

DISCUSSION

Recent studies have clearly demonstrated that highly enriched cultures can degrade unsubstituted aromatic compounds such as naphthalene without oxygen. Further understanding of the mechanisms of anaerobic naphthalene transformation and the bacteria responsible for the degradation activity, however, has been hampered by the lack of isolates. This is the first study presenting evidence of pure cultures capable of nitrate-dependent, anaerobic naphthalene degradation and mineralization.

The results obtained with nitrate-limited cultures demonstrated that nitrate was required for degradation of naphthalene by NAP-3-1 and NAP-4. There was no significant loss of nitrate or naphthalene in cell-free controls. Nitrate was required by both isolates NAP-3-1 and NAP-4 for significant transformation and partial mineralization of naphthalene. The minor loss of naphthalene in the nitrate-limited culture of NAP-4 (Fig. 1) may have been due to the presence of a small unquantified amount of nitrate left in the culture at the start of the experiment. In addition to demonstrating nitrate-dependent naphthalene degradation, the use of stringent anaerobic techniques in this experiment also precluded the possibility of any involvement of oxygen during naphthalene degradation. The nitrate-to-naphthalene stoichiometric ratio would be expected to be lower than the theoretical ratio of 9.6 if naphthalene mineralization were incomplete, as was the case here. Using the ¹⁴C incorporation into cell mass results and the likely nitrate reduction product, calculated stoichiometric ratios of nitrate-to-naphthalene utilization (using equations 1 and 2) were close to what would be expected from theory. For isolate NAP-3-1, the ratio was 30% higher than the expected ratio assuming denitrification to dinitrogen. Isolate NAP-4, which was not a denitrifier, demonstrated a higher molar ratio of nitrate utilization to the amount of naphthalene transformed than would be expected assuming denitrification. This result is

not unexpected if we assume nitrite is the product of nitrate reduction coupled to naphthalene oxidation by NAP-4. With this assumption, the cell mass incorporation data give a calculated nitrate-to-naphthalene ratio that was not significantly different than the observed amount.

The preceding cell energetics analysis assumes that nitrite is the terminal nitrate reduction product by NAP-4. Alternatively, isolate NAP-4 may have reduced nitrate to ammonia. With nitrate reduction to ammonia, the corresponding nitrate-to-naphthalene ratio for NAP-4 would be 2.8 mol/mol (with cell mass incorporation), a level much lower than the observed ratio of 12.4 or the predicted ratio of 11 with nitrate reduction to nitrite. Further, NAP-4 did not produce nitrous oxide or dinitrogen gas from nitrate. Although significant production of nitrite was observed in this culture during the denitrification assay, further studies are required to determine the nitrate reduction pathway employed by isolate NAP-4 during degradation of naphthalene.

The phylogenetic analysis was consistent with standard physiological and biochemical characterizations of the isolates. Isolate NAP-3-1 is a denitrifier related to *Pseudomonas* spp. in the gamma proteobacteria. The *Pseudomonas* family comprises many aerobic naphthalene-degrading bacteria. McNally et al. (22) reported biodegradation of naphthalene, acenaphthene, anthracene, phenanthrene, and pyrene in the absence of detectable oxygen by isolates putatively identified as *P. stutzeri*, *P. putida*, and *P. fluorescens*. Although the study by McNally et al. (22) did not prove nitrate-dependent naphthalene degradation, the results do suggest that other members of the *Pseudomonadaceae* may possess anaerobic PAH biodegradation ability, which is consistent with the results of this study.

Isolate NAP-4 also was in the gamma proteobacteria, but not closely related to NAP-3-1. NAP-4 was closely related phylogenetically to *Vibrio* spp. Phenotypically, *Vibrio* spp. are characterized by a lack of gas production (18), a finding also consistent with the results from the denitrification assay for the NAP-4 culture. Although some known marine *Vibrio* can degrade PAHs under aerobic conditions (13), none are known to degrade aromatic compounds under anaerobic conditions (27). Together with the NAP-3-1 results, these data suggest that

**FIG. 3.** Phylogenetic tree based on 16S rDNA sequences showing isolates NAP-4 and NAP-3-1 and other members of the gamma proteobacteria. The tree is the most parsimonious tree based on a branch and bound analysis using PAUP.
phylogenetically diverse bacteria within the gamma proteobacteria can degrade naphthalene without oxygen.

The isolation of the pure cultures obtained in this study was facilitated by the use of a highly enriched source of inoculum. The subcultures obtained from the FBR studies that were used as the source of inoculum in this study had been developed over a period of 2 years. Even with this extended enrichment period, the rate of naphthalene degradation was slow, necessitating the need for more readily utilisable carbon sources to assist in growth and isolation. Nitrate in marine sediment ecosystems is not thought to be a significant electron sink and, consequently, nitrate reducers are generally not considered important anaerobic organisms for significant removal of organic contaminants. The limited presence of these microorganisms in marine sediment may be one reason they have been overlooked as important contaminant degraders in the past.

Further studies are needed to determine what the biochemical mechanisms are for naphthalene degradation activity. The slow growth rates of our isolates on naphthalene and the resultant low cell mass production will make this task difficult. However, our technique of growing the cultures on alternate substrates (such as acetate) in the presence of naphthalene resulted in much higher cell mass production than when grown on naphthalene alone. This method could be used to facilitate experiments by increasing the cell mass. It is not possible to determine from the present data whether anaerobic naphthalene degradation is an intrinsically slow process or whether it is due to unknown growth-limiting factors. McNally et al. (22) reported anoxic PAH degradation rates comparable to or only slightly slower than aerobic degradation rates, including complete degradation of 24 μM naphthalene in 6 to 8 h. In contrast, Rockne and Strand (30) reported anaerobic specific PAH biodegradation rates that were an order of magnitude slower than other published aerobic rates. Elucidating the initial enzymatic attack on the ring structure may aid in determining the rate-limiting step of anaerobic PAH biodegradation. Recent work has shown that ring carboxylation is an early reaction of the anaerobic naphthalene and phenanthrene biodegradation pathways in a sulfate-reducing enrichment (38). It is unknown whether this pathway is also used by the cultures in this study to degrade naphthalene.

Our isolates may represent individual members of a consortium able to efficiently degrade naphthalene when present in coculture. Although NAP-4 is capable of naphthalene mineralization, it may degrade naphthalene or naphthalene intermediates more efficiently as a member of a consortium. For example, bacteria such as NAP-4, a nonnitrifying nitrate reducer, may transform naphthalene to utilisable substrates or may facilitate nutrient cross-feeding to other members of the microbial population. Consortium synergy may explain the difference between the slow degradation rates of our isolates and the rates observed in the FBR source of the isolate (30). In addition, there were similarities in the extent of naphthalene mineralization by the pure cultures in this study and those observed in the mixed enrichment subculture (the source of these isolates). Mineralization ranged from greater than 90% (for phenanthrene-fed subcultures) to 20% in the naphthalene-fed subcultures (Rockne and Strand, submitted); the latter result was similar to what was observed with both isolates NAP-4 and NAP-3-1. Interestingly, there was a large amount of naphthalene incorporated into the cell mass in the naphthalene-fed subcultures (Rockne and Strand, submitted), as was the case with NAP-4 but not NAP-3-1. The fraction of electron donor utilized for cell synthesis in the mixed culture was also in closer agreement with NAP-4 rather than NAP-3-1.

In summary, the isolates in this study are the first pure cultures shown to degrade naphthalene in the strict absence of oxygen using Hungate’s technique, resazurin, and chemical reductants. Naphthalene was mineralized in the absence of oxygen, and degradation was nitrate dependent. The bacteria capable of this metabolism were phylogenetically diverse within the gamma proteobacteria, suggesting that the ability to degrade naphthalene anaerobically may be widely distributed within this group. Further studies are required to determine the metabolic pathways of anaerobic naphthalene mineralization. This knowledge may help to identify potential cometabolites and/or cofactors required for rapid growth by the isolates and potential requirements for anaerobic naphthalene utilization in the environment.
